## 1

```
mod :: Int \rightarrow Int \rightarrow Int factors n = [x \mid x \leftarrow [1..n-1], mod <math>n x == 0]
```

This part of the code defines a list comprehension in which each element x is quarded with a comparison of mod and zero

The mod function allows only Int as arguments therefore the types look as follows:

```
factors :: Int -> [Int]
```

Since our function only accepts one type (Int) it's monomorphic

```
isPerfect n = sum (factors n) == n
```

Compares the sum of all factors and to the provided number returns a boolean the sum of factors can only be an Int, because factors accepts only Int (see above)

The comparison == returns a Bool

```
isPerfect :: Int -> Bool
```

isPerfect also accepts only one type (monomorphic)

```
insert _ n [] = [n]
insert 0 n l = n:l
insert i n (x:xs) = x : insert (i-1) n xs
```

Inserts a specific type into an array of the same type at the specified index

n doesn't have to be a specific type but the third argument has to be a list of the same type

```
insert :: Int -> b -> [b] -> [b]
```

since b can be of multiple types the function is polymorphic

```
mH(a, b, c) = c
```

mH has a tuple with three elements of which only the third is relevant

```
mH :: (a, b, c) -> c
```

since c can be multiple types the function is polymorphic (a,b are ignored anyway)

# 2

By implementing the square function

```
square n = n*n
```

we can query the type in ghci with

#### :t square

the output shows as that only the type Num is expected to use with \*

```
square :: Num a => a -> a
```

If we look at the documentation a  $\operatorname{Num}$  can be  $\operatorname{Int}$ ,  $\operatorname{Integer}$ ,  $\operatorname{Float}$ , and  $\operatorname{Double}$ 

Therefore the square function does not accept a Char
